## ABSTRACT

The National Household Education Survey (NHES) is a telephone survey of the noninstitutionalized civilian population of the United States that collects data on educational issues that are best explored through contact with households rather than with institutions. The NHES has been conducted in 1991, 1993, 1995, and 1996. In the 1996 NHES (NHES:96), the topical components were parent/family involvement in education and civic involvement. This working paper presents information on the unit response rates, item response rates, weighting procedures, and imputation procedures in the NHES:96. The description of the response and completion rates in the first section, "Unit Response Rates," includes data on the rates for the Screener interview, the Parent/Family Involvement/Civic Involvement interview, the Youth Civic Involvement interview, and the Adult Civic Involvement interview. The next section, "Item Response and Imputation Procedures for the NHES:96," discusses reasons for nonresponse and ways to handle missing data. Imputation of missing data was done to develop complete variables used in developing sampling weights and to enable users to compute estimates more easily. The final section, "Weighting and Standard Error Calculation Procedures for the NHES:96," describes the procedures used to produce the weights for use in estimating characteristics from the NHES:96 sample and for estimating the sampling errors of those estimates. (Contains 39 tables and 7 references.) (SLD)

The National Center for Education Statistics (NCES) is the primary federal entity for collecting, analyzing, and reporting data related to education in the United States and other nations. It fulfills a congressional mandate to collect, collate, analyze, and report full and complete statistics on the condition of education in the United States; conduct and publish reports and specialized analyses of the meaning and significance of such statistics; assist state and local education agencies in improving their statistical systems; and review and report on education activities in foreign countries.

NCES activities are designed to address high priority education data needs; provide consistent, reliable, complete, and accurate indicators of education status and trends; and report timely, useful, and high quality data to the U.S. Department of Education, the Congress, the states, other education policymakers, practitioners, data users, and the general public.

We strive to make our products available in a variety of formats and in language that is appropriate to a variety of audiences. You, as our customer, are the best judge of our success in communicating information effectively. If you have any comments or suggestions about this or any other NCES product or report, we would like to hear from you. Please direct your comments to:

## Foreword

Each year a large number of written documents are generated by NCES staff and individuals commissioned by NCES which provide preliminary analyses of survey results and address technical, methodological, and evaluation issues. Even though they are not formally published, these documents reflect a tremendous amount of unique expertise, knowledge, and experience.

The *Working Paper Series* was created in order to preserve the information contained in these documents and to promote the sharing of valuable work experience and knowledge. However, these documents were prepared under different formats and did not undergo vigorous NCES publication review and editing prior to their inclusion in the series. Consequently, we encourage users of the series to consult the individual authors for citations.

To receive information about submitting manuscripts or obtaining copies of the series, please contact Ruth R. Harris at (202) 219-1831 or U.S. Department of Education, Office of Educational Research and Improvement, National Center for Education Statistics, 555 New Jersey Ave., N.W., Room 400, Washington, D.C. 20208-5654.

## Overview of the National Household Education Survey

The National Household Education Survey (NHES) is a data collection system of the National Center for Education Statistics (NCES), which has as its legislative mission the collection and publication of data on the condition of education in the Nation. The NHES is specifically designed to support this mission by providing information on those educational issues that are best addressed by contacting households rather than schools or other educational institutions. The NHES provides descriptive data on the educational activities of the U.S. population and offers policymakers, researchers, and educators a variety of statistics on the condition of education in the United States.

The NHES is a telephone survey of the noninstitutionalized civilian population of the U.S. Households are selected for the survey using random digit dialing (RDD) methods, and data are collected using computer-assisted telephone interviewing (CATI) procedures. From 45,000 to 64,000 households are screened for each administration, and individuals within households who meet predetermined criteria are sampled for more detailed or extended interviews. The data are weighted to permit estimates of the entire population. The NHES survey for a given year typically consists of a set of screening questions, which collects household composition and demographic data, and extended interviews on two substantive components addressing education-related topics. In order to assess data item reliability and inform future NHES surveys, each administration also includes a subsample of respondents for a reinterview.

The primary purpose of the NHES is to conduct repeated measurements of the same phenomena at different points in time, although one-time surveys on topics of interest to the Department of Education are also conducted. Throughout its history, the NHES has collected data in ways that permit estimates to be tracked across time. This includes repeating topical components on a rotating basis in order to provide comparative data across survey years. In addition, each administration of the NHES has benefited from experiences with previous cycles, resulting in improvements to the survey procedures and content. Thus, while the survey affords the opportunity for tracking phenomena across time, it is also dynamic in addressing new issues and including conceptual and methodological refinements.

A new design feature of the NHES program implemented in the NHES:96 is the collection of demographic and educational information on members of all screened households, rather than just those households potentially eligible for a topical component. In addition, the expanded screener was designed to include a brief set of questions on an issue of interest to education program administrators and policymakers. In 1996, this topic was household use of public libraries. The total Screener sample size was sufficient to produce state estimates of household characteristics for the NHES:96.

Full-scale implementations of the NHES have been conducted in 1991, 1993, 1995, and 1996. Topics addressed by the NHES:91 were early childhood education and adult education. The NHES:93 collected information about school readiness and school safety and discipline. The 1991 components were repeated for the NHES:95, addressing early childhood program participation and adult education. Both components underwent substantial redesign to incorporate new issues, reflect methodological advancements since 1991, and develop new measurement approaches. In the NHES:96, the topical components were parent/family involvement in education and civic involvement. As noted above, the expanded screening feature included questions on household use of public libraries.

In addition to its topical components, the NHES system has also included a number of methodological investigations. These have resulted in technical reports and working papers covering

diverse topics such as telephone undercoverage bias, proxy reporting, and sampling methods. This series of technical reports and working papers provides valuable information on ways of improving the NHES and other surveys.

This working paper presents information on the unit response rates, item response rates, weighting procedures, and imputation procedures in the 1996 National Household Education Survey (NHES:96). Readers may also wish to review the other NHES:96 working papers: *Design, Data Collection, Interview Administration Time, and Data Editing in the 1996 National Household Education Survey* (Vaden-Kiernan et al. 1997), *Reinterview Results for the Parent and Youth Components of the 1996 National Household Education Survey* (Montaquila et al. 1997), *Undercoverage Bias in Estimates of Characteristics of Households and Adults in the 1996 National Household Education Survey* (Montaquila et al. 1997), and *Comparison of Estimates in the 1996 National Household Education Survey* (Nolin et al. 1997).

## 1996 National Household Education Survey Unit Response Rates

### Introduction

This report describes the response and completion rates for the NHES:96. It includes data on the rates for the Screener interview,<sup>1</sup> the Parent PFI/CI interview, the Youth CI interview, and the Adult CI interview. The following presentation assumes that the reader is familiar with the survey design and, to a lesser extent, the weighting procedures used in the NHES:96. The weighting procedures are discussed in a later section of this working paper, and the sample design is described in *Design, Data Collection, Interview Administration Time, and Data Editing in the 1996 National Household Education Survey*, (Vaden-Kiernan et al. 1997), *Reinterview Results for the Parent and Youth Components of the 1996 National Household Education Survey* (Montaquila et al. 1997), *Undercoverage Bias in Estimates of Characteristics of Households and Adults in the 1996 National Household Education Survey* (Montaquila et al. 1997), and *Comparison of Estimates in the 1996 National Household Education Survey* (Nolin et al. 1997).

Because there are a number of ways to describe the outcomes of the data collection activities of a random-digit-dial (RDD) telephone survey, the next section provides an introduction to the terms "response rate" and "completion rate" as used in this document and for the NHES in general. The results for the NHES:96 follow these introductory remarks.

### Definition of Response and Completion Rates

A response rate is the ratio of the number of units with completed interviews (for example, the units could be telephone numbers, households, or persons) to the number of units sampled and eligible for the interview. In some cases, these rates are easily defined and calculated based on known figures, while in other cases the numerators or denominators of the ratio must be estimated.

For reporting the results from the NHES:96, the response rate indicates the percentage of possible interviews completed taking all sampling stages into account, while the completion rate measures the percentage of interviews completed for a specific stage of the survey. For example, household members are identified in a two stage process for the Adult CI and Parent PFI/CI. Screener interviews are conducted to enumerate and sample household members, and then questionnaires are administered in a second-stage interview. If the responding household member fails to complete the first-stage Screener, no members can be sampled for other interviews. Under the design, the completion rate for the second stage (Parent PFI/CI or Adult CI) is the percentage of sampled persons who completed those interviews. The response rate is the product of the first- and second-stage completion rates.<sup>2</sup>

Response and completion rates can be either unweighted or weighted. The unweighted rate, computed using the raw number of cases, provides a useful description of the success of the operational aspects of the survey. The weighted rate, computed by summing the weights (usually the reciprocals of

---

<sup>1</sup> The Screener interview formed the basis of the Household & Library data file. The term "Screener" is used when referring to the interview, and "Household & Library data file" is used when referring to the data set.

<sup>2</sup> The calculation of the Youth CI response rate is described later.

the probability of selecting the units) for both the numerator and denominator, gives a better description of the success of the survey with respect to the population sampled. Both rates are usually similar unless the probabilities of selection and the response rates in the categories with different selection probabilities vary considerably. All of the response rates discussed in the report are weighted unless noted specifically in the text.

Response rates and completion rates are identical for the first stage of sampling and interviewing (*i.e.*, the Screener). The next section discusses the response rate for the Screener and provides a profile of the characteristics of the respondents. The discussion of response and completion rates for the Parent PFI/CI, Youth CI, and Adult CI interviews and response profiles for these interviews follow.

### **Screener Response Rates**

The first panel of table 1 shows the disposition of the 161,446 telephone numbers that were sampled for the NHES:96. The three major categories of response status are those identified as numbers for residential households, those identified as nonresidential numbers (primarily nonworking and business telephone numbers), and those numbers that, despite numerous attempts, could not be identified as residential or nonresidential.

About 47 percent of the telephone numbers were identified as residential. This percentage is similar to that reported for NHES:95, but lower than in previous NHES studies, which averaged about 60 percent. The difference may be partly attributable to a difference in the sampling methodology used. Both the NHES:95 and the NHES:96 used list-assisted sampling methods while earlier studies relied on the Mitofsky-Waksberg two-stage sampling methodology. One of the features of the list-assisted method is that the expected percentage of all telephone numbers that are residential is lower than in the Mitofsky-Waksberg two-stage samples that were used in NHES studies prior to 1995. Assuming that 40 percent of the telephone numbers with unknown residential status are residential (discussed below), the percentage of numbers that are residential is about 50 percent, close to the 49 percent that was expected at the start of the survey.

Prior to data collection, it was expected that Alaska and the District of Columbia would have residency rates that were lower than the country as a whole, and the samples in these states were supplemented to account for this. The observed residency rate for the District of Columbia was 32 percent (547 known residential telephone numbers out of 1,702) and the observed residency rate for Alaska was 33 percent (646 known residential numbers out of 1,947) (see table 4).

The percentage of telephone numbers with unknown residential status was about 6 percent, which is comparable to the percentage found in NHES:95 and slightly higher than the 3 to 5 percent found in previous NHES studies. Apparently, the sample of telephone numbers created using the list-assisted method contains more telephone numbers that cannot be identified as either residential or nonresidential despite numerous telephone calls. Since virtually all of the unknown residential status numbers were called 14 times or more as in previous NHES studies (see *Design, Data Collection, Interview Administration Time, and Data Editing in the 1996 National Household Education Survey* for more details on this issue), the percentage in this category is not the result of fewer calls to the numbers than in previous NHES studies.

The second panel of table 1 shows four estimated response rates for the Screener based upon different assumptions about the telephone numbers. Each of these rates is described below, along with

the rationale for its use. The difference among the rates is in the allocation of the numbers in the unknown residential status category.

The business office method derives its name from the technique used to estimate the denominator of the rate. A random sample of 350 telephone numbers with unresolved residency status were selected in the NHES:95 and the numbers were classified as either residential or nonresidential by calling local telephone companies. The telephone companies were asked to classify the numbers as working or not working. If they were working, the companies were asked to further identify them as residential or business numbers. As a result of this process, it is estimated that 40.5 percent of the numbers were residential. This result is nearly identical to the result from a study conducted at the end of the NHES:91. Therefore, the denominator of the business office method is all the telephone numbers that were known to be residences plus 40.5 percent of the numbers with an unresolved residential status. The numerator is the number of telephone numbers in households that participated in the survey.

The estimated Screener response rate using the business office method is 70 percent. If the raw count of telephone numbers was not weighted, the Screener response rate using the business office method would also have been 70 percent. The estimated Screener response rate of 70 percent is recommended for general use, and it is used in all the subsequent presentations of the data from the NHES:96.

The NHES:96 Screener response rate is lower than the 73 percent Screener response rate attained in the NHES:95. Both the NHES:95 and the NHES:96 have lower response rates than the earlier NHES collections; this may be due partly to the fact that a full household enumeration was requested early in the NHES:95 and NHES:96 Screeners. However, this does not explain the difference of about 3 percent between the NHES:95 and NHES:96 rates. One hypothesis is that the political climate of the winter of 1995-96 may have had an effect on NHES:96 response rates. Although we are unable to measure the impact of the political climate on the response rates, there are three factors to consider in this regard. First, the budget crises that evolved between the Congress and the administration reached a stalemate that led to two government shutdowns, neither of which was popular. The second of these two shutdowns encompassed the first two weeks of NHES:96 data collection. Second, the early stages of campaigning for the 1996 presidential election, as well as much-publicized activity on Capitol Hill, included attacks on the existence of the U.S. Department of Education and the Goals 2000 program. Finally, both at the state and national levels there has been increasing discussion of limiting legal immigration and stemming illegal immigration, as well as continued discussion of declaring English the "official" language of the United States; these factors may have depressed the response rates of Spanish-speaking persons, particularly if these issues are covered extensively in Spanish-language newspapers and television.

The other three response rates shown in table 1 were computed by allocating different proportions of the numbers with unknown residency status into the residential category. The CASRO (Council of American Survey Research Organizations) rate is computed by allocating the numbers with unknown residential status in the same proportion observed in the numbers with known residential status. Since evidence from checks done for the NHES:91 and the NHES:95 suggests that the residency rate for this set of telephone numbers is lower than implied by the CASRO rate calculation, we do not recommend using this assumption in the response rate calculation. The CASRO rate is 69 percent.

The conservative and liberal response rates define the lower and upper bounds of the response rate. The conservative response rate is computed assuming that all of the numbers with unknown residential status are actually residential numbers. The conservative rate is 65 percent. The liberal rate is computed

assuming that all the numbers with unknown residential status are actually nonresidential. The liberal rate is 73 percent.

For most purposes, it is reasonable to say that the Screener response rate is estimated to be between 65 and 73 percent, and that the best estimate is 70 percent. The variability in the estimates arises because it is not possible to identify precisely the residential status for each telephone number.

Table 2 provides a further breakdown of the participating and nonparticipating residential telephone numbers. The participating numbers are classified by whether or not any other interviews were scheduled for the household, and the nonparticipating numbers are classified by the reason for nonresponse. About 83 percent of all the nonresponse in the screening interview was due to an adult household member refusing to answer the screening items. This rate of refusal is about the same as the NHES:95 and the NHES:91, and higher than the NHES:93 rate of 68 percent. The next largest category is the 10 percent classified as maximum calls, which includes those households that never completed the Screener after numerous calls. While these households never explicitly refused to participate, potential respondents were not available to complete the screening items despite many attempts to reach them. Language problems account for 6 percent of nonresponse. The language problem cases are discussed in more detail below.

Table 3 shows the number of households in which extended interviews were scheduled. About 95 percent of sampled telephone numbers were allocated to parent and youth interviewing, and 5 percent were allocated to adult interviewing. This distribution is reflected in the percentages of households with completed screening interviews. Virtually all of the households in the adult sample had one adult selected for the Adult CI interview. In the parent/youth sample, 16 percent had only a Parent PFI/CI interview scheduled, 21 percent had both Parent PFI/CI and Youth CI interviews scheduled, and 64 percent had no extended interview scheduled.

### ***Profile of Screener Response Rates***

In most RDD surveys, it is difficult to obtain and examine the characteristics of those households that do not respond to the screening interview. Consequently, the ability to examine nonresponse bias at this stage of the survey is limited. In this section, we discuss the Screener response rates by state, noting those with higher and lower response rates. Following this, we address response rates by characteristics of the geographic area of the households (the ZIP Code that has the most households associated with telephone numbers in the exchange) based on the 1990 Census of Population.

Table 4 gives the distribution of the telephone calls and the estimated response rate by State. The response rates range from 61 percent to 83 percent. States with their populations concentrated in urbanized areas (such as California, the District of Columbia, New York, and New Jersey) tended to have lower response rates, while the less urbanized bread basket states (such as South Dakota, Montana, North Dakota, Wyoming, Iowa, and Nebraska) tended to have higher response rates. This pattern is common in telephone surveys.

Table 5 gives the distribution of the telephone calls and the estimated response rate by the characteristics of the areas. For example, areas with less than 11 percent of the adult population having a college degree as of the 1990 Census had a response rate of 73 percent, while areas with 26 percent or more college graduates had a response rate of 67 percent. Response rates for the Pacific and Mid-Atlantic divisions, areas with high concentrations of population in urbanized areas, are lowest, while

response rates for the West North Central and East South Central divisions, areas with lower proportions of the population in urbanized areas, are highest. This pattern is also seen in the response rates by metropolitan status, where the response rate for non-metropolitan areas is highest. This is the same general pattern that was observed in the State response rates. Households living in low-minority areas completed the Screener at higher rates than those living in high-minority areas. The response rates were also higher in areas with higher proportions of children.

This univariate profile of Screener response rates by the characteristics of the areas is difficult to interpret because there are so many characteristics to consider. In addition, some of the characteristics are correlated, and the univariate profile does not explore these relationships. Consequently, a multivariate analysis was performed to examine the interrelationship of the characteristics and the response rates.

The goal of the multivariate analysis was to determine if any groups of households had extremely low response rates. Nonresponse bias in the estimates may appear when the characteristics of the respondents and nonrespondents are different. By identifying groups with different response rates, the characteristics of the respondents and nonrespondents can be used as an indicator of the potential for nonresponse bias. The characteristics of the geographic areas corresponding to the telephone numbers sampled were used to identify groups with different response rates. The variables included in the analysis were characteristics of the geographic areas described above that were available and thought to be correlated with the response rate.

The analysis was done using a categorical search algorithm called CHAID. This algorithm is very similar to the continuous search algorithms LISREL and AID (Automatic Interaction Detector) which have been used for a number of years, but it is designed especially to handle categorical data like that available for the NHES:96. The procedure divides the entire data set into cells by attempting to determine sequentially the cells that have the greatest discrimination with respect to the response rates. In other words, it attempts to divide the data set into groups so that the response rate within cells is as constant as possible and the response rate between cells is as different as possible. This automatic procedure was done by specifying that the minimum number of households in any group had to be greater than or equal to 500 and the split of the variables into subgroups had to be statistically significant using a chi-square test at the 95 percent significance level.

An example may help to explain the methods used in CHAID. All of the characteristics in the model are tested and the one with the response categories having the largest discrimination with respect to the response rates is identified. Looking at table 6, which contains the summary of this analysis, the first column indicates that Census division was the variable chosen as most associated with differential response rates and all 10 response categories for this variable were retained. Note, for example, that within Census divisions the data were tested and metropolitan status was then used to split the data. The process continued until the final 27 cells shown in the table were formed. The table is formatted so that the order of the column variables closely corresponds to the order in which they entered the model. Although the variables percent low income, median years education, and percent owner occupied were considered in the CHAID analysis, they were not found to be discriminators of response in this multivariate analysis.

Since many of the variables in the CHAID model, such as Census division, have multiple response categories, the program must take this into account. The CHAID software does this in two ways. First, it allows the data set to be split into more than one subgroup at a time. For example, metropolitan status categories are split differently within different Census divisions. Second, the procedure follows a

relatively complex procedure to check all binary splits of the data and equalize the chance of selecting variables irrespective of the number of response categories that variable may have.

The results of the analysis are given in table 6. As noted above, each cell was constrained so that it contained at least 500 observations. The completion rates in the last column of the table, that is, the weighted counts of the number of participating households divided by the number of households (participating and not participating), vary from about 56 percent to 83 percent in the 27 cells.

The first question that needs to be addressed is whether or not the variability in response rates by cells is large. One way of looking at this problem is to consider what could be expected if 27 cells were defined randomly rather than by trying to maximize the difference in response rates. Forming random cells with as few as 500 cases and given the overall response rate of 70 percent, it would not be unusual to find a range in the response rates across the cells from 66 to 74 percent (which are close to the conservative and liberal response rates shown in table 1). Comparing this with the observed range of 56 to 83 percent suggests that the CHAID model that attempts to maximize variation in response rates has discriminated well.

The range of response rates among the 27 cells suggests that the key characteristics identified by CHAID should be used in creating weighting adjustments. Otherwise, there is evidence that the response bias may be large for these characteristics. As described in the weighting section of this report, the variables urbanicity (highly correlated with metropolitan status), race of first adult in the household, home tenure, and an indicator of whether children are present in the household were used in forming cells for raking adjustments. Separate raking adjustments were computed for each state. While the use of these variables is important and positive, it does not imply the estimates are free of nonresponse bias. Clearly, some nonresponse bias exists, but these results suggest that the weighting adjusts for some of the important characteristics associated with the response bias.

Another observation that sometimes indicates problems in telephone surveys is the comparison of the percentage of households or persons eligible for the survey to the percentage eligible from other data sources, such as the Current Population Survey (CPS). As shown in table 7, estimates from the October 1994 CPS showed that about 38 percent of households had children eligible for the Parent interview (i.e., children between 3 years of age and 12th grade). However, the sample design for NHES:96 assumed that about 30 percent of households had children eligible for the Parent interview, based on the October 1992 CPS (for more details, refer to *Design, Data Collection, Survey Administration Time, and Data Editing in the 1996 National Household Education Survey*, Vaden-Kiernan et al. 1996). Estimates from the October 1993 CPS indicate that about 33 percent of households had children eligible for the Parent interview. We are unable to explain the variation in the CPS estimates. The percentage of households in the NHES:96 that had children eligible for the Parent interview was 33 percent (23 percent with at least one child between age 3 and 5th grade, and 18 percent with at least one child between 6th and 12th grade). This percentage falls within the range of the estimates obtained from the October 1992, October 1993, and October 1994 CPS surveys (that is, 30 percent to 38 percent). As a result, we see no strong indications of screener nonresponse bias due to differential response between households with children and households without children.

This type of analysis can be extended to better understand the nature of the potential nonresponse bias from the screening of households by comparing the general characteristics of the households from the completed NHES:96 to the same characteristics from the CPS. Table 8 gives household and person distributions from all 55,838 households with completed Screeners from the NHES:96 and from the March 1995 CPS. The NHES:96 counts were based on the number and characteristics of all persons

enumerated in the household. Percentages reflect households (e.g., percent of households with one person, etc.). The household and person characteristics examined were those thought to be correlated with nonresponse based on prior NHES studies.

In terms of household composition, households with only one member and households with older adults are often the most difficult to survey. The table shows that the percentage of 1-person households enumerated in the NHES:96 was 1.7 percentage points less than the CPS estimate. Breaking these households out by sex<sup>3</sup>, the difference between the NHES:96 estimate and the CPS estimate is about the same for both sexes. The percentage of households with at least one adult aged 65 years or more is also slightly lower in the enumerated NHES:96 than the CPS estimate. These results are consistent with the hypothesis that these households are less likely to participate in surveys than other types of households. It also suggests that the NHES:96 estimates may be somewhat biased due to these differences, although the sampling weights for the components were adjusted for some of these characteristics.

The second part of the table shows the percentage distribution of households containing persons in given age ranges from the two surveys. The largest differences are for estimates of the percentage of households with persons 0 to 2 years old and for the percentage of households with persons 60 years or more. The difference for the older persons is related to the household distribution mentioned above. It may also reflect reporting errors in the NHES:96. Some respondents may fail to include grandparents if they believe that the interviewer is only concerned with the nuclear family. The under-representation of households with persons 0 to 2 years old may be related to the fact that the NHES:96 is a survey about education. Households with no members currently in school may think the survey does not apply to them and respond at a lower rate than those in households with school-age children.

None of the comparisons reveal any differences of large magnitude between the respondents to the NHES:96 and the general population. However, the results do show some smaller, but important, differences that may result in biases in some of the estimates from the survey, such as those focusing on the elderly. The differences discovered here are very similar to the results from the NHES:95 survey.

### ***Language Problem Resolution***

The NHES:96 was conducted in English and in Spanish. The questionnaires were translated into Spanish, a Spanish version of the CATI instrument was programmed, and bilingual interviewers were trained to complete the interview in either English or Spanish.

When a telephone number is dialed in an RDD survey, the telephone may be answered by someone who does not speak English. These contacts are typically coded by interviewers as "language problem" cases and classified as contact with a person with a hearing or speech problem or one who speaks a language other than English. If the respondent speaks a language other than English and the interviewer recognizes the language, the language is also recorded by the interviewer.

In the NHES:96, all cases classified as a language problem, including those with hearing and speech problems, were placed in a separate work category so that only trained, bilingual interviewers could access them for follow-up calls. If a bilingual interviewer encountered a Spanish-speaking respondent in the initial contact, the interviewer immediately began to conduct the interview in Spanish.

---

<sup>3</sup> An examination of the percentage of single-female households was prompted by a concern that such households may be less likely to participate in surveys in which information on household composition is collected.

These cases were coded as having been worked in Spanish but were not classified as having been language problem cases. Such cases are quite rare; only 3 Screeners were completed in this way in the NHES:96.

Language problem cases include a wide range of situations that result when a non-English-speaking person (or a speech or hearing impaired person) answers the telephone. For example, some households have members who speak English and other members who do not. In this case, the classification of the household as a language problem may depend on who answers the telephone for a specific call. Another possibility is that all household members speak English, but the telephone might be answered on some occasions by a person who does not live there and does not speak English. A second call to the household might be answered by an English-speaking household member. The procedures followed in the NHES:96 to attempt to obtain completed Screeners for cases classified as language problems are described in *Design, Data Collection, Interview Administration Time, and Data Editing in the 1996 National Household Education Survey* (Vaden-Kiernan et al. 1997).

The results for Screener interviews that were ever classified as having a language problem are presented in table 9. The first section gives the results for those cases ever classified as hearing or speech problems. The second and third sections of the table concern language problem cases other than hearing or speech problems. The second section includes cases in which the interviewer reported that the respondent in the initial household contact was speaking Spanish. The third section includes cases in which the initial interviewer reported that the respondent was speaking a language other than Spanish or English. It should be noted that the interviewers were not trained to recognize the language of the respondent; they were merely asked to record what they thought the language spoken might have been.

There were 545 Screeners that were classified by at least one interviewer as a hearing or speech problem. About one-fourth of these cases were eventually completed, either because another household member answered the phone or because the interviewer initially misclassified the case. Of the 128 completed Screeners in this group, 12 were completed in Spanish.

The response rate for the 2,395 cases classified by the initial interviewer as Spanish-speaking was slightly lower than the overall rate for the Screener. This finding is contrary to the NHES:95, in which households initially believed to be Spanish speaking responded at higher rates than the national sample as a whole. About 66 percent of all these cases were finalized as completes in the NHES:96. About 92 percent of these cases were completed in Spanish, indicating the initial interviewers did an excellent job initially identifying the language spoken by the respondents as Spanish.

The reason for the difference in response among Spanish-speaking respondents between the NHES:95 and the NHES:96 is not evident. The distribution of nonresponse cases does not suggest that higher rates of refusal occurred among these households. In previous NHES administrations, most (but not all) Spanish-language interviewing was done from an Oceanside, California, facility, and this was not true in the NHES:96. However, we do not believe that a difference in using east-coast rather than west-coast interviewers could account for the difference in response. Both new and experienced interviewers have been used at both east coast and west coast telephone interviewing centers, and all interviewers receive the same type of training. Possible differences exist in dialects or accents of the interviewers, but the use of standard Spanish CATI screens eliminates much of the interviewer effect. As noted earlier, growing public debate about immigration and "official language" may be a factor, but we would not expect to see such a large difference over a period of one year.

The last section of table 9 shows that the completion rate for the 960 cases identified as speaking some language other than English or Spanish was only about 17 percent. A low completion rate for these types of cases was expected since the interview was conducted only in English and Spanish. Of the completed Screeners in this class, the number completed in English was more than twice as large as the number completed in Spanish.

### **Parent PFI/CI, Youth CI, and Adult CI Interview Response Rates**

During the screening interview, all household members were enumerated. After the enumeration, samples of children or adults within the household were selected for the Parent PFI/CI and/or Youth CI, or Adult CI components. For the sampled children, the person who was the most knowledgeable about the child's care and education (nearly always a parent, and most often the child's mother) became the respondent for the Parent PFI/CI interview. For older children sampled for the Youth CI interview and for adults sampled for the Adult CI interview, the interview was conducted only with the sampled person.

Table 10 presents the number of children enumerated, the number sampled, and the final status distribution for the Parent PFI/CI interview, along with the estimated completion and response rates. Since the study design precluded conducting more than two Parent PFI/CI interviews in the same household, some eligible children were not sampled. Of the enumerated 47,829 children eligible for sampling in the Parent PFI/CI component, a sample of 23,835 children was selected. About 2 percent of the sampled children were not actually in the age and grade range for the survey as determined by the Parent PFI/CI interview respondent. These children were classified as ineligible. Complete interviews were obtained for 20,792 of the sampled children for an estimated 89 percent completion rate. This completion rate is similar to those attained in the School Safety and Discipline (SS&D) and School Readiness (SR) components of the NHES:93, the NHES survey with parent interviews for children of the most comparable age range. When multiplied by the Screener response rate, the overall response rate for the Parent PFI/CI interview is 63 percent.

The number of older children enumerated, sampled, and the final status distribution for the Youth CI interview are also given in table 10. About 70 percent of the 15,560 enumerated older children were sampled for the Youth CI interview. Less than 2 percent of the sampled older children were classified as ineligible because their parent reported that they were not actually enrolled in grades 6 through 12. In all, 8,043 interviews were completed with the sampled youth. The estimated completion rate for the Youth CI interview is 76 percent. The estimated response rate is 53 percent which is the product of the Screener response rate and the Youth CI completion rate.<sup>4</sup>

The Youth CI interview condition completion rate for the NHES:96 (the percentage of interviews completed once the preceding parent interview was completed) was 86 percent compared to 92 percent for the Youth interview of the NHES:93 SS&D component. One possible explanation for the decrease is that explicit parental consent was required for the Youth CI interview in the NHES:96 but was not required for the NHES:93 Youth interview. In the NHES:96, about three-fourths of all refusals to the Youth CI interview came from parents (702 out of 955 refusals), and not from youth themselves.

The bottom section of table 10 gives the numbers of adults enumerated and sampled and the final status distribution for the Adult CI interview. In the adult sample, one adult per household was sampled

---

<sup>4</sup> Note that the Youth CI response rate reflect parental nonresponse and parental refusal to permit the Youth CI interview. Both types of cases were included in the denominator of the Youth CI completion rate.

randomly. A total of 2,250 adults completed the Adult CI interview. Almost all of those sampled were eligible for the interview; those classified as ineligible were either in the military or currently enrolled in high school. The estimated Adult CI interview completion rate is 84 percent and the overall response rate is 59 percent. This completion rate is nearly the same as the completion rates attained in the Adult Education (AE) component of the NHES:95 and the NHES:91.

The reasons for nonresponse for the various components are presented in table 11. Respondent refusal to complete the interview accounted for about 62 percent of parent nonresponse and about 64 percent of adult nonresponse. The second most common cause of nonresponse for parents and adults was the inability to reach the respondent. This includes maximum call cases that may, in some cases, have been "hidden" refusals in which the respondent was avoiding the interview.

A different distribution of reasons for nonresponse is seen for the Youth CI interview. The leading cause of nonresponse for the Youth CI interview was inability to complete the Parent PFI/CI interview; completion of the Parent PFI/CI interview was a necessary condition for conducting the Youth CI interview. The second most common source of nonresponse was refusal to do the Youth CI interview. As noted above, about three-quarters of refusals to the Youth CI interview came from parents who declined to give permission for the youth to respond.

Language and other miscellaneous problems (e.g., respondent was ill or otherwise unavailable during the data collection period) accounted for less than 9 percent of the total nonresponse to the Parent PFI/CI, Youth CI, and Adult CI interviews.

### ***Profile of Parent PFI/CI, Youth CI, and Adult CI Interview Completion Rates***

The completion rates for the Parent PFI/CI, Youth CI, and Adult CI interviews can be examined by variables available for both respondents and nonrespondents. The four variables available for the Parent PFI/CI interview are census region (based on the telephone number), sex of the sampled child, age of the sampled child, and grade (if enrolled in school) of the sampled child. All of these items except census region were collected during the Screener. Table 12 shows the number of sampled children by response status and completion rate for each of these variables. The range of completion rates is from 77 to 93 percent. The completion rates are quite consistent across all the levels of census region and sex. In general, completion rates decrease as age and grade increase. This suggests the potential for nonresponse bias; however, the use of grade in creating weighting class adjustments for nonresponse (See the weighting section of this report) should reduce nonresponse bias. Since age is highly correlated with grade, the use of both variables for weighting was not necessary.

For the Youth CI interviews, five variables about each sampled youth are available for examining the response profile: census region, sex of the sampled child, age of the sampled child, highest educational attainment of a parent, grade of the child, and type of school (i.e., public vs. private). Census region was obtained based on the phone number; sex, age, and grade were obtained from the screener; and parental educational attainment and type of school were obtained from the Parent PFI/CI interview. The number of cases for these variables and the completion rates are shown in table 13.

There is little variation in the completion rates for region. The completion rates for age and grade increase through age 14 and 8th grade, and decrease slightly thereafter. Parents of younger youth were less likely to give consent than parents of older youth. This had the effect of increasing completion rates as age/grade increased. An opposite effect was due to the fact that older youth were harder to reach at

home, which resulted in a decline in completion rates with increasing age/grade. These highly variable rates could be indicative of potential bias. To reduce the bias in the estimates, nonresponse adjustment groups based on the classification of the sampled youth by grade were used in producing the weights for estimation. This procedure is especially important for the Youth CI interview because the overall response rate is lower for the Youth CI interview than for the other interviews. Completion rates for the Youth CI interview increased as parental educational attainment increased, suggesting that parents with higher educational attainment were more likely to cooperate in the survey about their children's education. The completion rate for youth enrolled in public school was higher than that for youth enrolled in private school, and both rates were considerably higher than that for youth who are schooled at home. However, the completion rate for home schoolers is based on a relatively small number of sampled youth.

For the Adult CI interview, four variables from the screener were considered in examining the response profile: sex, age, marital status, and highest educational attainment (table 14). The completion rate for females was slightly higher than that for males. Completion rates decreased as age increased. This is consistent with the hypothesis that the elderly, who are less likely to have children enrolled in school, are less likely to participate in a survey sponsored by an education agency. Separated and divorced adults cooperated at a higher rate than others. As was the case with the Parent PFI/CI interview, completion rates for the Adult CI interview increased as the educational attainment of the adult increased. To reduce bias due to extended interview nonresponse, the variables sex, marital status, and educational attainment were used to form weighting class adjustment cells for nonresponse adjustment. Age was not used in the Adult CI nonresponse adjustment; because of the relatively small sample size for this interview, the numbers of cases in the adjustment cells were too small when age was included.

## **Unit Response Rate**

### **Tables 1 - 14**

Table 1.—Number of telephone numbers dialed by residential status and Screener response rates

Screener response category	Number	Percentage of all numbers	Percentage of residential numbers
Total.....	161,446	100.0	
Identified as residential.....	76,258	47.2	100.0
Participating.....	55,838	34.6	73.2
Not participating.....	20,420	12.6	26.8
Identified as nonresidential.....	75,736	46.9	
Unknown residential status.....	9,452	5.9	
Screener response rates*	Rate (Percent)		
Estimated response rate (using business office method).....	69.9		
CASRO response rate.....	69.1		
Conservative response rate.....	65.4		
Liberal response rate.....	73.4		

\* All the response rates use the weighted number of participating households as the numerator. The denominators vary but are all estimated totals: for the estimated response rate using the business office method, the proportion of unknown residential status numbers included in the denominator was based upon the proportion identified in checks with telephone business offices; for the CASRO (Council of American Survey Research Organizations) response rate, the proportion of unknown residential status numbers included in the denominator was based upon the residency rate for the numbers with known residential status; for the conservative response rate, all of the unknown residential status numbers were included; for the liberal response rate, none of the unknown residential status numbers were included.

NOTE: Because of rounding, details may not add to totals.

## **Item Response and Imputation Procedures for the NHES:96**

### **Introduction**

In the NHES:96, as in most surveys, the responses to some data items were not obtained for all interviews. There are numerous reasons for item nonresponse. Some respondents do not know the answer for the item or do not wish to respond for other reasons. Some item nonresponse arises when an interview is interrupted and not continued later, leaving items at the end of the interview blank. Item nonresponse may also be encountered because responses provided by the respondent are not internally consistent and this inconsistency is not discovered until after the interview is completed. In these cases, the items that were not internally consistent were set to missing ("not ascertained").

### **Methodology**

For most of the data items collected in the NHES:96, the item response rate was very high. For the Screener, the median response rates for imputed items were 94.97 percent for household-level characteristics (including library items) and 99.48 percent for person-level characteristics. For the Parent PFI/CI, Youth CI, and Adult CI questionnaires the median item response rates for imputed items were 99.08 percent, 99.38 percent, and 99.47 percent, respectively. Response rates for items pertaining to income are lower than for other items, due to the highly sensitive nature of income questions. Another set of items that sometimes exhibit low response rates are those that few respondents get a chance to answer. The items about parents who do not live with their sampled children (referred to as nonresidential parents) are good examples of this. For rarely asked items such as these, one or two missing values could result in a low item response rate.

Despite the overall high item response rate, virtually all data items with missing data (i.e., responses not ascertained, "don't know" responses, and refusal to respond to the particular question) were imputed. For the public release files, the exceptions were the political knowledge items where "refused" and "don't know" responses are of analytic interest and are thus treated as responses. Character string variables, such as countries of origin, languages, or "other/specify" responses were also not imputed. These character string variables do not appear on the public use data files, however, they may be obtained in restricted use data files available through a special licensing agreement with NCES.

Imputation was done for two reasons. First, complete responses were needed for variables used in developing the sampling weights. Second, users will be computing estimates using a variety of methods and complete responses should aid their analyses.

A hot-deck procedure was used to impute most missing responses. (See the discussion of manual imputation, below, for exceptions.) For this approach, the data file was sorted into cells defined by characteristics of the respondents. These characteristics, or boundary variables, were used to group respondents into those most likely to have the same response for the data item to be imputed. Two types of boundary variables were used. "Hard" boundary variables were considered to be so important that the donor and the recipient were required to match exactly. For other sort variables, called "soft" boundary variables, the values did not have to match exactly. In effect, the hard boundary variables were matching variables and the soft boundary variables were used to order the cases within the matching variables. The WESDECK software was used to implement the hot-deck imputation procedure.

For variables which were sometimes skipped, a “trigger” variable was included as one of the hard boundary variables. The trigger variable ensured that the skip pattern in the questionnaire was maintained. The trigger variable could be either a single variable or a set of conditions that determines whether the respondent is eligible for the particular question, i.e. whether the variable in question should be answered or skipped. In some cases, an item was originally coded -1 (inapplicable) because of nonresponse to a component of the trigger variable, but the item became applicable as a result of the imputed value for the trigger component. In such cases, the item was recoded from -1 to -9 and imputed. If, on the other hand, the trigger indicates that the item should be skipped, the variable was set equal to -1 (if it wasn’t already equal to -1) prior to running WESDECK.

When item response rates are low, the potential bias due to item nonresponse is of particular concern. If item response propensities vary substantially across levels of a particular characteristic, then that characteristic should be used in forming cells for hot-deck imputation, in order to reduce the bias due to item nonresponse. The characteristics used to form the cells for hot-deck imputation included items that were expected to be predictors of response propensity for the particular characteristic.

Having been sorted into cells defined by the boundary variables, the observations were divided into two groups within the cells depending on whether or not the item was missing. The donors consisted of observations with complete data for the item; recipients were observations for which the item was missing. Whenever a case with a missing value was encountered, the value of the data item from a randomly selected donor within the same cell was imputed for the missing item. This method is called a hot-deck procedure because donors are selected from the current data set, as opposed to some pre-defined set of allowable values. The distribution of each variable before and after hot-deck imputation was reviewed to ensure that the imputed data did not significantly alter the distribution.

For each data item that was imputed, an imputation flag variable was created. If the response for the item was imputed, then the imputation flag was set equal to a value between 1 and 4, where a 1 indicates hot-deck imputation without any preliminary recoding necessary, 2 indicates hot-deck imputation with preliminary recoding from -1 to -9, 3 indicates manual imputation, and 4 indicates that the original response was -8 (“don’t know”). For values that were not imputed, the imputation flag was set to zero. The flag enables users to identify imputed values and the method of imputation used. If desired, the user can then delete the imputed values, use alternative imputation procedures, or account for the imputation in the computation of the reliability of the estimates produced from the data file. The flag value of 4 was set so that users can consider “don’t know” responses to items separately from other nonresponse. This may provide analytic utility in the analysis of variables such as FSHADMEE, FSHADCN, FSHADBAC, FSHADPTA, FSHADCOU, FSHADCN, FHHOME, FHSHARE, HNDOWHN, HNDNTIST, and HNDNTWHN on the Parent PFI/CI File, and PRSTUGOV, SAARRSER, and SAREQSER on the Youth CI File (This list of variables is provided for illustrative purposes only, and is not all-inclusive.).

### **Manual Imputation**

Manual imputation was used in the NHES:96 for five purposes. The first was to impute Parent interview variables for children who are home schooled. Secondly, manual imputation was used to impute variables that involved complex relationships that would have required extensive programming to impute using a hot-deck procedure. A third use of manual imputation was to correct for inconsistent imputed values following post-imputation data editing. Fourthly, it was used to impute for a few cases

when no donors with matching hard boundary variable values could be found. The final use of manual imputation was to impute person-level characteristics from the Screener. Each of the reasons for manual imputation are discussed below along with the methods used in the imputation. The percentages of imputed cases that were manually imputed for each item are given tables 2 (person-level variables from the household-Screener), 4 (household characteristics from the Screener), 8 (Parent PFI/CI items), 12 (Youth CI items), and 16 (Adult CI items).

For home schoolers, Parent PFI/CI interview variables were imputed manually. The skip patterns for home schoolers (FIPATH=H) in the Parent PFI/CI interview were very different from those used for other children. Additionally, many Parent PFI/CI interview questions did not apply to home schoolers. Because of this and the small number of home schoolers for which a Parent PFI/CI interview was completed (244), the home schoolers' missing items were imputed manually. For the most part, donors for imputing items for home schoolers were chosen among the other home schoolers with the same grade. One exception to this rule occurred when imputing items about nonresidential parents. For these items, donors were chosen among home schoolers of the same age.

When a household member's relationship to the child was missing, the variable RELATN(*n*) was imputed manually. A survey manager reviewed a printout containing a listing of the age, gender, and relationship of all household members to the subject child in order to determine a reasonable imputed value for the missing RELATN(*n*). Manual imputation was used here because this examination of complex relationships would have required extensive programming.

Following imputation, edit programs were run to ensure the imputed responses did not violate edit rules. A small number of edit failures and skip problems was identified as a result, and an update was made to the data file by manually imputing the problem item. The distribution of the item in question was used to arrive at the new values. A small number of imputed values that were inconsistent were deleted and imputed manually.

For a small number of variables, hot-deck imputation failed for a few cases when no donors with matching hard boundary variable values could be found. For these cases, if relaxing the hard boundary variable requirements still did not produce a donor, manual imputation was done. The distribution of the complete data for each item was used to assign imputed values. The standard hard and soft boundary variables<sup>5</sup> used to impute in WESDECK were not always used to control the manual imputation process; however, the recipient's reported values for other correlated variables were taken into consideration to ensure consistency of the imputed data.

Person-level characteristics from the Screener were imputed manually because the reasonableness of imputed values for these person-level characteristics can often be assessed by examining the values of these variables for other members of the household. For example, while there is an increasing incidence of mixed-race households, the race of household members tends to be the same in most cases. Education is also correlated among adults within households. The use of the manual imputation approach permitted the review of the characteristics of household members when imputing the missing values on the person-level variables.

For manual imputation of person-level characteristics, three sort variables were utilized. State was used as a hard boundary variable, and 3-digit ZIP code and person identification number were used as

---

<sup>5</sup> A standard set of variables was used for each data file. These are discussed in the following sections.

soft boundary variables. Because all household members share the first 8 digits of their identification numbers, sorting by person identification number resulted in all household members being grouped together. The specifications for each variable indicated whether within-household or outside-household imputation was done.

### **Updates and Imputations**

Some of the values changed during the manual imputation process were actually updates. This occurred when a value was missing in the Screener, but was available from another source in the database. For example, when an adult had a missing value on the variable  $\text{GRADE}(n)$  (highest education), the database was checked to see if that person was the mother or father of a sampled child and, if so, the value of  $\text{MOMGRADE}$  or  $\text{DADGRADE}$  (as appropriate) was used to update  $\text{GRADE}(n)$ . Conversely, when  $\text{GRADE}(n)$  was available for the mother or father but  $\text{MOMGRADE}$  or  $\text{DADGRADE}$  had missing values, the value of  $\text{GRADE}(n)$  (for the appropriate person) was used to update  $\text{MOMGRADE}$  or  $\text{DADGRADE}$ . Very few values were updated in this way, since most such updates had been made prior to data extraction and the post-extraction process was just an additional check. In general, this process was not considered imputation because the response was obtained from the household. The exception was when neither variable had a reported value. In such cases, one variable (e.g.,  $\text{GRADE}(n)$ ) was imputed, and the imputed value was copied into the other variable (e.g.,  $\text{MOMGRADE}$ ); likewise, the value of the imputation flag for the first variable was copied into the value of the imputation flag for the second variable.

### **Variables for Weighting and Imputation**

Certain variables were imputed first so that they could be used to create cells for weighting class adjustments and for hot-deck imputation. The Screener variable  $\text{HNUMUSE}$  was used to adjust household-level weights for the number of telephones in the household. The Screener variables  $\text{HOWNHOME}$ ,  $\text{HZIPCODE}$ ,  $\text{HINCOME}$ ,  $\text{RACE}(n)$ , and  $\text{HHAGE}(n)$  were used in forming cells for raking the household-level weights and person-level weights for the extended interviews (for Parent PFI/CI and Youth CI interviews, the child's age calculated from year of birth was substituted for  $\text{HHAGE}(n)$ ). The Screener variables  $\text{SGRADE}(n)$  and  $\text{SGRDEQ}(n)$  for the sampled child were used to form nonresponse adjustment cells for the Parent weights, while  $\text{HISPAN}(n)$  for the sampled child was used in forming cells for raking the Parent weights. The Parent PFI/CI interview variables  $\text{GRADE}$  and  $\text{GRADEEQ}$  were used to form nonresponse adjustment cells for the Youth weights and raking cells for both the Parent and Youth weights. The person-level Screener variables  $\text{MARITL}(n)$ ,  $\text{GRADE}(n)$ , and  $\text{SEX}$  were used to form nonresponse adjustment cells for the Adult weights, and  $\text{SEX}$  was also used in forming raking cells for the Adult weights.

For imputation of household-level items from the Screener, the variables  $\text{GRADE}(n)$ ,  $\text{SDIPL}(n)$ ,  $\text{HHAGE}(n)$ , and  $\text{HOWNHOME}$  were used in forming the boundary variables for imputation of other items;  $\text{GRADE}$ ,  $\text{SPUBLIC}$ ,  $\text{SEX}$ ,  $\text{MOMGRADE}$ ,  $\text{DADGRADE}$ ,  $\text{MOMDIPL}$ ,  $\text{DADDIPL}$ ,  $\text{MOMTYPE}$ , and  $\text{DADTYPE}$  were used to form the boundary variables for imputation of items from the Parent PFI/CI interview; the variables  $\text{GRADE}$ ,  $\text{SPUBLIC}$ ,  $\text{SEX}$ ,  $\text{MOMGRADE}$ ,  $\text{DADGRADE}$ ,  $\text{MOMDIPL}$ , and  $\text{DADDIPL}$  were used to form the boundary variables for imputation of items from the Youth CI interview; and  $\text{AGE}$ ,  $\text{AGRADE}$ ,  $\text{ADIPL}$ ,  $\text{SEX}$ , and  $\text{CAPARENT}$  were used to create boundary variables for imputation of items from the Adult CI interview. Each of these variables had to be imputed before imputation of the corresponding component could proceed. In cases in which a sort variable within a

given file had missing values for some cases, all other sort variables without missing values were used to impute the sort variable with missing values prior to continuing with subsequent stages of imputation.

## **Screener Questionnaire**

As discussed in Section 1, person-level items from the Screener were imputed manually. The household-level variables XHHACTV, XHHBORN, and XHHLANG were also imputed manually, since they were fully determined by the responses to corresponding person-level items. Note that since many Screener items were copied to extended interview files, response rates for such items are given for the extended interview file as well as for the Screener; the response rates given for the extended interview file correspond to the subset of cases contained in the file. The following is a description of the rules used to manually impute person-level Screener items.

### **Person-Level Items**

If a Parent PFI/CI interview was completed for a child with missing age from the Screener, then the age of the child was computed from the child's month and year of birth reported during the Parent PFI/CI interview. This was treated as an update rather than an imputation. Otherwise, characteristics such as grade (for an enrolled child) or relation (for a person other than an enrolled child) were used in combination with the sort variables (state, 3-digit ZIP code, and person identification number) to find a donor. For adults in households where no Parent PFI/CI interview was completed, the distributions of ages of adults (within the household, if available; otherwise, within 3-digit ZIP code) was used to impute age.

Sex was imputed manually in one of two ways. A deterministic approach was used when the characteristics of the household members suggested an appropriate answer. In cases where the available information did not clearly suggest an appropriate answer, the file was sorted by the sort variables (state, 3-digit ZIP code, and person identification number) and sex was alternately imputed as male or female.

Whenever possible, the person's race, country of birth, and first language were imputed from donors within the same household. When donors were not available in the same household, the file was sorted by the sort variables and a member of a contiguous household (or the nearest household with a response to the item) was used as a donor.

Marital status was imputed using a deterministic approach based on the characteristics of the household members. Detailed rules were developed for this purpose based on the number of adults in the household, gender of adults, age, etc. Current enrollment and, if applicable, home schooling (yes/no), grade in school (including grade, grade equivalent, year of vocational school, year of college, and year of graduate school), full-time or part-time enrollment, and public or private enrollment were imputed using as the donor the nearest person of the same age as the case with the missing value. High school diploma and highest grade completed were imputed from a donor within the same household whenever possible; otherwise, the nearest donor (subject to criteria such as age, grade, etc.) outside the household was used.

Table 1 shows the item response rates for Screener person-level items. Response rates for these items are all over 90 percent, and ACTVDU(*n*) (the active duty military indicator) had a 100 percent response rate. As discussed in Section 1, all imputation of person-level Screener items was done manually, and the number of cases imputed for each item is shown in table 2.

## Household-Level Items

For the most part, household-level items from the Screener were imputed using WESDECK. The standard set of hard boundary variables for most household-level Screener items consisted of STATE, *HIGRADR*, and the trigger variable. *HIGRADR* is a variable derived from *GRADE(n)* and *SDIPL(n)* which classifies households according to the highest educational attainment level of any household member (less than high school diploma, high school diploma but no bachelor's degree, college graduate). Within each cell created by the hard boundary variables, the household records were sorted by *KIDINHH* and *HOWNHOME* (owned or rented home). *KIDINHH* is a variable that indicates whether children under 18 years old are present in the household; this variable was derived from the AGE of each household member. *HIGRADR* and *KIDINHH* were created for use in imputation only and do not appear on the public data files.

Table 3 shows the item response rates for the household-level (as opposed to person-level) items in the Screener, including the library items. Table 4 lists the few variables that were imputed manually (Most of the household-level variables were imputed using the hot-deck procedure.). Table 5 lists those items that had a response rate of less than 90 percent. These variables can be grouped into two categories: those related to community size and those related to household income. Community size items might have low response rates because respondents may have had difficulty estimating the population of the suburb or city in which they live. Household income items traditionally generate high nonresponse because many people are sensitive about providing information about their household income, and prefer to respond with a general income range; the item response rate for *HINCMEXT* (household income to the nearest thousand) is just slightly more than half that for *HINCMRNG* (\$25,000 or less/more than \$25,000).

## Parent PFI/CI Questionnaire

The standard set of hard boundary sort variables for most items consisted of *MAINRSLT*, *GRADE*, *SPUBLIC*, and the trigger variable. Within each cell created by the hard boundary variables, the sampled Parent PFI/CI interview records were sorted by *SEX*, *PARGRADES*, and *HHPARNS*. *PARGRADES* is a variable created from *MOMGRADE*, *DADGRADE*, *MOMDIPL*, and *DADDIPL* which classifies cases according to the highest educational attainment of any parent or guardian living in the household (less than a high school diploma, high school diploma but no bachelor's degree, college graduate). The variable *HHPARNS* is a variable that identifies the household as comprising both a mother and a father, or otherwise. *HHPARNS* was derived from the variables *MOMTYPE* and *DADTYPE*. The variables *PARGRADES* and *HHPARNS* were created for use in imputation only, and do not appear on the public data files.

For imputation of *SETHNIC*, the variables *RACE* and *HISPANIC* were used as hard boundary variables in addition to *MAINRSLT* and *SPUBLIC*. Data from previous studies (such as the National Educational Longitudinal Survey) have shown that black children tend to attend schools that have high proportions of blacks (i.e., their own race), while this homogeneity tends not to be as pronounced for children of other races.

*AGE95* was used as an additional soft boundary variable for imputing the items *NRLSTNUM*, *NRLSTUNT*, *NRLIVNUM*, and *NRLIVUNT*. Since these items refer to the length of time since the sampled child had contact (of various types) with the nonresidential parent, the use of *AGE95* as a sort

variable helped to ensure reasonableness in the imputed values and thus avert edit failures. For example, an 8 year old child should not be imputed to have last lived with a nonresidential parent 12 years ago.

Table 6 shows the item response rates for imputed variables from the Parent PFI/CI questionnaire. Most of these response rates were over 90 percent. Table 7 shows the response rates for variables from the Parent PFI/CI interview public release file that were not imputed. Table 8 presents all variables on the Parent PFI/CI interview file that were imputed manually and the corresponding percent imputed manually.

Table 9 shows the Parent PFI/CI public file items having response rates of less than 90 percent. These items included some addressing parents' reports of school practices to involve parents (i.e. FSHADMEE, FSHADPTA, FSHADCOU), questions about involvement of the non-residential parent (i.e. NRADOPTV, NRLIVNU2), and income questions. The low response rates for income items and for questions about the nonresidential parent are probably due mainly to sensitivity toward these types of questions. Furthermore, in some cases, parents lack knowledge of the involvement of their child's nonresidential parent.

### **Youth CI Questionnaire**

The standard set of hard boundary sort variables for items on the Youth CI file consisted of GRADE, and SPUBLIC. The soft boundary variables were SEX and PARGRADS. For variables involved in skip patterns, a trigger variable was added as a hard boundary variable in order to maintain the skip pattern. *PARGRADS* was created for use in imputation, and is defined as specified above for the Parent PFI/CI data file.

Tables 10 and 11 present the item response rates for the Youth CI interview public release file items that were imputed and those that were not imputed, respectively. Table 12 lists any variable on the Youth CI interview file that was imputed manually and gives the percent imputed manually. This table includes variables from the Screener and Parent PFI/CI interviews that were copied onto the Youth CI interview file for analysis purposes (e.g., SEX, RACE, MOMTYPE, DADTYPE).

Table 13 shows the Youth CI public file items with response rates less than 90 percent. The items SASCHLYR and SANEXTYR pertain to future participation in a service activity. Some respondents had difficulty "committing" to a yes/no answer when asked if they would participate in any kind of community service activity before the end of the school year or next year. Reasons for low response rates for household income and community size items were given in Section 3.

### **Adult CI Questionnaire**

The hard boundary sort variables used for imputing all items on the Adult CI file were *AGECAT* and *AGRADER*. The soft boundary variables were SEX and CAPARENT. For variables involved in skip patterns, a trigger variable was added as a hard boundary variable in order to maintain the skip pattern. *AGECAT* and *AGRADER* were created for use in imputation. *AGECAT* is a categorical variable based on AGE, with categories 18 to 29 years, 30 to 49 years, and 50 years or more. *AGRADER* was created using AGRADE and ADIPL, and classifies persons according to their educational attainment (less than high school graduate, high school diploma but no bachelor's degree, college graduate).

Tables 14 and 15 present the item response rates for Adult CI interview public release file variables that were imputed and those that were not imputed, respectively. Table 16 lists those variables that were imputed manually. As in the other components, this table includes variables from the Screener that were copied onto the Adult CI file for analysis purposes (e.g., AGE, RACE, XHHBORN, HINCNEXT).

Table 17 shows the Adult CI items with response rates less than 90 percent. These items are all household income and community size questions; reasons for low response to these items were given in Section 3.

## Weighting and Standard Error Calculation Procedures for the NHES:96

### Introduction

This document describes the procedures used to produce the weights for use in estimating characteristics from the 1996 National Household Education Survey (NHES:96) sample and for estimating the sampling errors of those estimates.

The NHES:96 utilized a random digit dial (RDD) sample of telephone numbers in the 50 States and the District of Columbia, with interviews conducted from January through April 1996. The objective of the study is to make inferences about the entire civilian, noninstitutionalized population. For this reason, the estimates derived from the sampled telephone households are adjusted to totals that include both telephone and nontelephone households.

Telephone numbers were randomly sampled in the 50 States and the District of Columbia. Telephone numbers in some states were sampled at a higher rate to obtain a minimum of 500 completed household screening interviews in each state. The 161,446 sampled telephone numbers were randomly divided into two groups: one of the groups (referred to as the parent/youth sample) was administered the Parent PFI/CI and Youth CI interviews if there were eligible household members; the other group (referred to as the adult sample) was administered the Adult CI interview if there were eligible household members.

The survey consisted of a screening interview and extended interviews with sampled members of the screened households. The data collected in the screening interview may be used to produce state-level estimates of the characteristics of the households. During the screening interview, the respondent provided information on household members that was used to determine whether anyone in the household was eligible for an extended interview. The three extended interview components of the NHES:96 are the Parent PFI/CI, the Youth CI, and the Adult CI components. The Parent PFI/CI component included children from 3 years of age through twelfth grade, provided the child was under 21 years of age. The Parent PFI/CI interview was conducted with the parent or guardian who knew the most about the sampled child's care and education. The Youth CI component included children enrolled in grades 6 through 12; Youth CI interviews were conducted with the sampled youth directly with no exceptions. For the Adult CI component, interviews were conducted with adults 18 years and older who were not currently enrolled in secondary school and were not on active duty in the U.S. Armed Forces.

In the sections that follow, the weighting and variance estimation methodologies for the NHES:96 are described in detail. The computation of household-level weights for use in analyzing the screener data is described in the next section. Subsequent sections describe the computation of the person-level weights for use in analyzing the extended interview data. The last section describes the procedures for computing sampling errors. More detailed information on the sample design for NHES:96 is contained in *Design, Data Collection, Interview Administration Time, and Data Editing in the 1996 National Household Education Survey* (Vaden-Kiernan et al. 1997), and more information about the unit response rates for the NHES:96 is given in Unit Response Rates section of this report.

## Household-Level Weights for the Screener Interview

The NHES:96 was the first NHES study in which the expanded screener interview was fully implemented. The enhanced data collection associated with the screener interview introduced new statistical issues for the NHES, such as producing household-level estimates at both the state and national levels along with person-level estimates at the national level consistent with those that have been produced for each of the previous administrations of the NHES. With the new screener, data on households and the members of the household are available from all sampled households, not just those households in which persons were sampled for extended interviews. The screener also contains items on household public library use.

The household-level weight is the product of four factors:

- (1) the weight associated with the oversampling of telephone numbers in states with fewer residential telephone numbers ( $A_j$ );
- (2) the weight associated with the oversampling of telephone numbers in high minority exchanges ( $B_j$ );
- (3) the weight associated with the number of telephone numbers in a household ( $C_j$ ); and
- (4) a raking adjustment to adjust for screener nonresponse and to compensate for the fact that only telephone households were eligible for the NHES:96 survey ( $D_j$ ).

Both the parent/youth sample and the adult sample were included in the computations of these weighting factors. Special steps would have been taken if there were indications that the response rates in these subsamples were very different.

The procedures for computing the household-level weights are given below.

1. The RDD sampling method used for the NHES:96 is a list-assisted method described by Brick et al. (1995). This basic method was also used in the NHES:95. The method used for NHES:96 was a single stage sample where 161,446 telephone numbers were sampled from strata defined by state. In 33 states, the telephone numbers were sampled at a rate proportional to the number of telephone numbers in the state. In the 18 states where the sample was expected to produce fewer than 500 completed screener interviews, telephone numbers were sampled at higher rates in an effort to obtain at least 500 completed screener interviews.

Households were assigned a weight adjustment to account for the oversampling by state. The adjustment factor is the oversampling rate given in table 1. Households in a state where oversampling did not occur were given an adjustment factor of 1. The actual probability of selection was the inverse of the base sampling rate times this factor. Since the base rate was a constant and adjustments to control totals were used, the constant was suppressed for this step of weighting. Let

$$A_j = \frac{1}{x_i} \quad \text{if household } j \text{ is in state } i, \text{ and oversampling occurred in state } i, \text{ where } x_i$$

is the factor for oversampling given in table 1, and

$$A_j = 1 \quad \text{if household } j \text{ is in state } i \text{ and no oversampling occurred in state } i.$$

2. Within each state, telephone numbers were divided into two strata, high and low minority, by telephone exchange. The high minority stratum was defined to include those exchanges with 20 percent or more Black or 20 percent or more Hispanics in the population. In some states, there were no, or very few, high minority exchanges; oversampling was not done in these states (see table 1; states in which oversampling of high minority exchanges was not done have a sampling factor of 1.000 for high minority exchanges). Telephone numbers in high-minority exchanges were sampled at a rate approximately twice that of the low-minority exchanges. Therefore, households in the high minority stratum were given a weighting factor  $B_j$ . This factor is presented in table 1. Households in the low minority stratum were assigned an adjustment factor of 1. Some oversampling rates are not exactly 2.000 and some adjustment factors are not exactly 0.500. This is because some state/minority strata had odd numbers of telephone numbers; thus the rate at which telephone numbers were sampled in high minority exchanges was slightly more than twice the sampling rate in low minority exchanges in some states.
3. A weighting factor of unity was assigned to households reporting one telephone number in the household. An adjustment factor of 1/2 was assigned to households with more than one residential telephone number<sup>6</sup>. Technically, if the other telephone number(s) of households with multiple residential telephone numbers is in the zero-listed stratum, the household should get a weight adjustment of 1. However, the practice of looking up the other phone numbers in these households is impractical and the percent of such numbers in the zero-listed stratum is small. Let

$$C_j = \frac{1}{2} \quad \text{if household } j \text{ has more than one telephone number, and}$$

$$C_j = 1 \quad \text{if household } j \text{ has one telephone number.}$$

If a household was sampled twice through two different telephone numbers, only one of the interviews was kept in the sample. The interview that was not kept was assigned a result code indicating that it is a "duplicate." The interview that was kept has  $C_j$  set equal to unity, to reflect that it was sampled twice.

The household-level base weight for household  $j$ ,  $UHW_j$ , is the product of the three factors described above. It can be written as:

$$UHW_j = A_j * B_j * C_j.$$

---

<sup>6</sup> The weight could be modified by a factor equal to the reciprocal of the number of residential telephone numbers in the household, but the adjustment by a factor of 2 is thought to be somewhat better. Massey and Botman comment on this adjustment in "Weighting Adjustments for Random Digit Dialed Surveys", in Telephone Survey Methodology, pp. 145-146.

4. The final step in household weighting was to adjust UHW<sub>j</sub> to known state control totals in order to account for household-level nonresponse and undercoverage due to sampling only telephone households. Raking procedures within each state and the District of Columbia were used to accomplish this task.

Up to four variables were used for raking the household weights. These variables are: (1) race of the oldest adult in the household, (2) home tenure (rented or owned/other), (3) whether children under 18 years of age are present in the household, and (4) urbanicity (urban/rural). These variables were selected because they are available at the state level from existing sources and are correlated with coverage loss from telephone sampling and response propensity.

In some states all four variables were used for raking; in other states only three of the variables were used. Race was not used in some states because of the very low numbers of expected completed interviews with nonwhite persons in the state (see below). The categories of race also varied across states based on the distribution of the population in the given states (also described below). Decisions about which of the variables to use in each state were made based on the requirement for the expected number of completed Screeners to be at least 50 in each raking cell for each state. Using this criterion, the following decisions were made:

- For ID, IA, KS, KY, ME, MN, MT, NE, NH, ND, OR, RI, SD, UT, VT, WV, and WY, the variables child present, home tenure, and urbanicity were used. Race was not used in these states because it was expected that fewer than 50 completed Screeners would be obtained in the "nonwhite" race category.
- For AL, AK, AZ, AR, CO, CT, DE, GA, HI, IN, LA, MD, MA, MI, MS, MO, NM, NC, OH, OK, PA, SC, TN, VA, WA, and WI, the variables child present, home tenure, urbanicity, and race (categorized as white/non-white) were used. In these states, the number of sample cases in the black category or the all other race category was expected to be less than 50.
- For CA, FL, IL, NJ, NY, and TX, the variables child present, home tenure, urbanicity, and race (categorized as white/black/all other) were used.
- For DC and NV, the variables child present, home tenure, and race (categorized as white/non-white) were used. Urbanicity was not used, since DC is entirely urban. In Nevada, urbanicity was not used because of small cell sizes for the "rural" category.

The control totals of the number of households for each state were obtained from the March 1995 CPS. The number of households for each cell of the dimensions needed for raking was computed by applying the percentage distributions from the 1990 Census of Population within each state to the March 1995 CPS totals. This allocation procedure was necessary because the number of households from the 1990 Census of Population is too out-of-date, and March CPS has too small a sample to provide reliable state level estimates for the raking control totals. The control totals are listed in table 2.

Before raking, the 130 households in the NHES:96 sample that were comprised entirely of active duty military personnel were excluded. All of the variables from the NHES:96

interview used in raking were fully imputed. Raked weights are formed by iteratively modifying the household-level weights until they correspond to the state-level control totals. A table of estimates is formed using the household-level weights. The household-level weights are multiplied by the constant that will force the sum of the tabled values to equal the state-level control totals along the first dimension. The revised table is then multiplied by the constant required so that the second dimension totals are obtained, and the same process is repeated for the third dimension (and for the fourth dimension, for those states where a fourth dimension was used). When the last dimension is done, one iteration of raking is complete. Further iterations were employed so that the estimates converged to the control totals across all the dimensions. The iterations were continued until all the tabled totals were within one of the control totals across all dimensions for each state.

The final household-level weight for household  $j$ ,  $HHW_j$ , is given by:

$$HHW_{j(c)} = UHW_j * D_c,$$

where  $D_c$  is the raking adjustment factor described above for adjustment cell  $c$ , where household  $j$  has the attributes corresponding to the levels of the dimensions of the raking cell  $c$  for the given state.

### Person-Level Weights for the Parent PFI/CI Interview

In sampling younger children for the Parent PFI/CI interview, every sampled household with a child from age three through 5th grade was included with certainty. Similarly, in sampling older children for the Parent PFI/CI interview, every sampled household with a child in grades 6 through 12 was included with certainty. This section describes the development of the person-level weights for the Parent PFI/CI interview.

All of the age-eligible children in the household who were enrolled in 12th grade or below and under age 21 were potential subjects for the Parent PFI/CI interview, but not all were sampled. One, and only one, younger child was sampled from every household with a younger child. One, and only one, older child was sampled from every household with an older child. The parent or guardian most knowledgeable about the care and education of the sampled child was asked to complete the Parent PFI/CI interview for that child. The Parent interview weight for sampled child  $k$  in household  $j$ ,  $PW_k$ <sup>7</sup>, is the product of the household weight and four weight adjustment factors:

- (1) the weight associated with sampling telephone numbers where the Parent PFI/CI and Youth CI interviews were administered ( $A_{jk}$ );
- (2) the weight associated with sampling a child within each household ( $B_{jk}$ );
- (3) the weight associated with Parent interview nonresponse ( $C_k$ ); and
- (4) the adjustment associated with raking the person-level weights for the Parent interview to Census Bureau estimates of the number of children ( $D_k$ ).

---

<sup>7</sup> The household factor  $j$  is suppressed here for ease of presentation.

The procedures for computing the person-level weight adjustments from the Parent PFI/CI interview are given below.

1. As described earlier, telephone numbers were randomly divided into two groups: one of the groups was used to sample persons for the Parent PFI/CI and Youth CI interviews, and the other group was used to sample persons for the Adult CI interview. A total of 95 percent (19 out of 20) of all the sampled telephone numbers was randomly sampled and assigned to the parent/youth sample. The remaining telephone numbers were assigned to the adult sample. The first weight adjustment reflects this differential sampling rate. The adjustment can be written as:

$$A_{jk} = \frac{20}{19} \quad \text{for all } k \text{ children in household } j.$$

2. The second weight adjustment accounts for the probability of sampling child  $k$  from among the children in household  $j$ . This adjustment is the inverse of the probability of selecting the child. The sampling adjustment for younger children (*i.e.*, those age 3 years through 5th grade) depends on the number of younger children in household  $j$  ( $Y_j$ ). One younger child was selected from among the  $Y_j$  younger children in the household. Therefore, the adjustment for a sampled younger child can be written as:

$$B_{jk} = Y_j \quad \text{for a sampled younger child } k \text{ in household } j.$$

The adjustment for sampling older children (*i.e.*, those enrolled in grades 6 through 12, and no more than 20 years old) follows the same procedure, where  $O_j$  is the number of older children in household  $j$ . The adjustment for a sampled older child is:

$$B_{jk} = O_j \quad \text{for a sampled older child } k \text{ in household } j.$$

For each sampled child  $k$ , the unadjusted person-level weight,  $UPW_k$ , can be written as the product of the household weight and these two adjustments.

$$UPW_k = HHW_j * A_{jk} * B_{jk},$$

where the subscript for the household has been suppressed in  $UPW_k$  for ease of presentation.

The unadjusted Parent interview weights,  $UPW$ , were examined and the amount of variability in the weights was greater than desired due to the earlier stages of weighting. To reduce the variability in the final weights, the weights were trimmed before adjusting for nonresponse. In all, 183 cases with unadjusted Parent weights in excess of 10,000 (the mean unadjusted Parent interview weight was 2,513) were trimmed to be equal to 10,000. The trimmed weight is denoted  $UPW^*$ .

3. The next step was to adjust for parents/guardians who did not respond to the Parent PFI/CI interview for the sampled children. Each sampled child was classified as either a respondent (R) or a nonrespondent (NR), depending on whether or not the parent/guardian responded to the Parent PFI/CI interview for the sampled child. The trimmed, unadjusted Parent weights ( $UPW^*$ ) of the nonresponding children were distributed to the trimmed unadjusted Parent

weights of the responding children within a nonresponse adjustment cell. The adjustment cells were formed according to the grade of the sampled child (table 3). Each grade was its own adjustment cell. Children enrolled in school but classified as “ungraded” or “no grade equivalent” were kept as a separate cell for nonresponse adjustment. Although there were only 5 respondents in this cell, it was feared that the bias incurred by combining these cases with other cells would be greater than the increase in variance due to the smallness of this cell. The nonresponse adjustment factor,  $C_{k(c)}$ , applied to each respondent  $k$  in adjustment cell  $c$  is:

$$C_{k(c)} = \frac{\sum_{h \in R_c \cup NR_c} UPW_h^*}{\sum_{h \in R_c} UPW_h^*}$$

Thus, for each sampled child  $k$ , the nonresponse adjusted person-level weight,  $NPW_k$ , can be written as:

$$NPW_{k(c)} = UPW_k^* * C_{k(c)}.$$

4. The final step in adjustment was to adjust the nonresponse adjusted Parent interview weight,  $NPW$ , to national control totals using a raking procedure. This additional raking adjustment, following the household-level raking adjustment, is required because the Parent PFI/CI interview involves new eligibility criteria and a new level of sampling. Three dimensions were used for raking the Parent interview weights. The first dimension is a cross of race/ethnicity of the child and household income categories; the second dimension is a cross of Census region and urbanicity; and the third dimension is a cross of home tenure and the grade of the child. These variables were selected because they are available from existing sources and are correlated with coverage loss from telephone sampling and response propensity. The same variables were used for raking 9- and 10-year olds in the NHES:95 ECCP component, except that age was used in the NHES:95 ECCP, while grade was used here. Prior to raking, the variables used in the raking procedure were fully imputed. For the purpose of raking, children enrolled in school but classified as “ungraded” or “no grade equivalent” were assigned the modal grade for their year of age.

The control totals for each dimension are listed in table 4. The control totals of the number of children were obtained from the March 1995 CPS and allocated according to the October 1994 CPS distributions. In other words, the number in a raking cell is the proportion in that cell from the October 1994 CPS multiplied by the estimated total from the March 1995 CPS. For example, the proportion of children who are in 5th grade and live in rented homes was estimated from the October 1994 CPS and then multiplied by the total number of children from the March 1995 CPS to give the control total for this cell. This allocation was necessary because the raking dimensions use items that are only available in the October CPS while the number of children obtained from the March 1995 CPS is more accurate since it is closer in time to the 1996 survey date. The 1990 Census of Population distribution was used to estimate the distribution of persons across cells defined by urbanicity and Census region, in order to be consistent with the procedure used for the household weight. The raking iterations were continued until the estimated totals were within 1 of all the control totals.

The final Parent interview weight for sampled child  $k$  is:

$$PW_{k(c)} = NPW_k * D_{k(c)} ,$$

where  $D_{k(c)}$  is the raking adjustment factor for raking cell  $c$ , where child  $k$  has the attributes corresponding to the levels of the three dimensions of raking cell  $c$ .

### Person-Level Weights for the Youth CI Interview

As described above, one, and only one, older child was selected in every parent/youth sample household that has a child age 20 or less enrolled in grades 6 through 12. A Youth CI interview was conducted with each sampled older child if and only if the Parent PFI/CI interview for that child was completed. This prevented the interviewing of a minor without the knowledge of his/her parent, and provided parents with experience with the survey content prior to giving permission. Youths who did not live with a parent/guardian or with an adult at least 12 years older than the sampled youth were declared ineligible for the Youth CI interview. This section describes the development of the person-level weights for the Youth CI interview.

The Youth interview weight for sampled older child  $k$ ,  $YW_k$ , uses the nonresponse adjusted Parent interview weight for the older child,  $NPW_k$ , as the base weight. Two weight adjustments were made to  $NPW_k$  to produce  $YW_k$ . These are:

- (1) the adjustment associated with Youth interview nonresponse ( $A_k$ ); and
- (2) the adjustment associated with raking the Youth interview weights to Census Bureau estimates of the number of older children ( $B_k$ ).

The procedures for computing the Youth interview weights are given below.

1. The first weight adjustment to NPW adjusts for sampled older children for whom the Parent PFI/CI interview was completed but the Youth CI interview was not completed. Each sampled older child with a completed Parent PFI/CI interview was classified as either a respondent (R) or a nonrespondent (NR) to the Youth CI interview. The weights of the nonresponding older children are distributed to the weights of the responding older children within a nonresponse adjustment cell. The adjustment cells were formed based on the grade of the sampled older child (table 5). Each grade was its own adjustment cell. The nonresponse adjustment factor,  $A_k$  for each adjustment cell is:

$$A_{k(c)} = \frac{\sum_{h \in R_c \cup NR_c} NPW_h}{\sum_{h \in R_c} NPW_h}$$

Thus, for each sampled older child  $k$  with a completed Parent PFI/CI interview, the nonresponse adjusted Youth interview weight,  $NYW_k$ , can be written as:

$$NYW_{k(c)} = NPW_k^* * A_{k(c)}.$$

The variability in the Youth interview weights was examined to determine whether trimming would be desired. The variability was not sufficient to justify trimming.

2. The final step is to adjust NYW to national control totals using a raking procedure. Three dimensions were used for raking the Youth interview weights. The first dimension is a cross of race/ethnicity of the older child and household income categories; the second dimension is a cross of Census region and urbanicity; and the third dimension is a cross of home tenure and the grade of the older child. These variables were selected because they are available from existing sources and are correlated with coverage loss from telephone sampling and response propensity. The same variables were used for raking 9- and 10-year olds in the NHES:95 ECCP component, except that age was used in the NHES:95 ECCP, while grade was used here. Prior to raking, the variables used in the raking procedure were fully imputed. The dimensions and control totals are listed in table 6.

The control totals of the number of children were obtained by allocating the estimate of the total number of older children from the March 1995 CPS to the October 1994 CPS distributions (table 6). In other words, the control total for a raking cell is the proportion in that cell from the October 1994 CPS multiplied by the estimate of the total from the March 1995 CPS. This allocation is necessary because the raking dimensions use items that are only available in the October CPS while the number of children obtained from the March 1995 CPS is more accurate since it is closer in time to the 1996 survey date. The 1990 Census of Population distribution was used to estimate the distribution of persons across cells defined by urbanicity and Census region.\* Note that although the same variables were used in raking the Parent and Youth weights, the control totals for the two were different. This was due to the difference in age eligibility for the two components. The raking iterations were continued until the estimated totals were within 1 of all the control totals.

The final person-level weight for the Youth CI interview for each sampled older child  $k$  is:

$$YW_{k(c)} = NYW_k * B_{k(c)} ,$$

where  $B_{k(c)}$  is the raking adjustment factor for raking cell  $c$ , where child  $k$  has the attributes corresponding to the levels of the three dimensions of raking cell  $c$ .

### Person-Level Weights for the Adult CI Interview

In sampling adults for the Adult CI interview, every sampled household in the set of telephone numbers sampled for this interview that had an eligible adult was included with certainty. An eligible adult is defined to be a person 18 years of age or older who is not enrolled in 12th grade or below and is not on active duty in the U.S. Armed Forces. This section describes the development of the person-level weights for the Adult CI interview.

All of the eligible adults in the household were potential subjects for the Adult CI interview, but not all were sampled. One and only one adult was sampled from every household with an eligible adult. The weight for the Adult CI interview for adult  $k$  in household  $j$ ,  $AW_k$ , is the product of four weight factors:

---

\* The 1990 Census figures were used to be consistent with the procedure followed for treating the household weight.

- (1) the weight associated with sampling households where the Adult CI interviews were administered ( $A_{jk}$ );
- (2) the weight associated with sampling an adult within each household ( $B_{jk}$ );
- (3) the weight associated with Adult interview nonresponse ( $C_k$ ); and
- (4) the adjustment associated with raking the Adult interview weights to Census Bureau estimates of the number of adults ( $D_k$ ).

The procedures for computing the person-level weights from the Adult CI interview are given below.

1. As described earlier, the sample of telephone numbers selected in the NHES:96 sample was randomly divided into two groups: one of the groups was administered the Parent PFI/CI and Youth CI interviews, and the other group was administered the Adult CI interview. A total of 95 percent of all the sampled telephone numbers was randomly sampled and assigned to the parent/youth portion of the sample. The remaining telephone numbers were assigned to the adult sample. The first weighting factor associated with the Adult interview weight adjusts for this differential sampling rate. The adjustment can be written as:

$$A_{jk} = 20 \quad \text{for adult } k \text{ in household } j.$$

2. The second weighting factor accounts for the probability of sampling an adult  $k$  from among the eligible adults in household  $j$ . This factor depends upon the number of eligible adults in household  $j$  ( $RA_j$ ); it is the inverse of the probability of selecting the adult. One adult was selected from among the  $RA_j$  eligible adults in the household. Therefore, the adjustment for a sampled adult can be written as:

$$B_{jk} = RA_j \quad \text{for a sampled adult } k \text{ in household } j.$$

For each sampled adult  $k$ , the unadjusted person-level weight,  $UAW_k$ , can be written as the product of the household weight and these two factors. That is,

$$UAW_k = HHW_j * A_{jk} * B_{jk},$$

where the subscript for the household has been suppressed in  $UAW_k$  for ease of presentation.

3. The next step was to adjust for adults who did not respond to the Adult CI interview. Each sampled adult was classified as either a respondent (R) or a nonrespondent (NR). The weights of the nonresponding adults were distributed to the weights of the responding adults within a nonresponse adjustment cell. As shown in table 7, three variables were used to form the adjustment cells: Gender of the adult, marital status of the adult (currently married/not currently married), and the highest educational attainment of the adult (no high school diploma and no additional education/completed high school and may have attended or completed vocational school or attended some college including attaining an associate's

degree/attained a bachelor's degree or higher degree). The nonresponse adjustment factor,  $C_k$ , for each adjustment cell was computed as follows:

$$C_{k(c)} = \frac{\sum_{h \in R_c \cup NR_c} UAW_h}{\sum_{h \in R_c} UAW_h}$$

Thus, for each sampled adult  $k$ , the nonresponse adjusted person-level weight,  $NAW_k$ , can be written as:

$$NAW_{k(c)} = UAW_k * C_{k(c)}.$$

The variability in the Adult interview weights was examined to determine whether trimming would be desired. The variability was not sufficient to justify trimming.

4. The final step was to adjust  $NAW$  to national control totals using a raking procedure. Four dimensions were used for raking the Adult interview weights (table 8). The first dimension is a cross of race/ethnicity of the adult and household income categories; the second dimension is a cross of age categories and gender; the third dimension is a cross of Census region and urbanicity; and the fourth dimension is home tenure. These variables were selected because they are available from existing sources and are correlated with coverage loss from telephone sampling and response propensity. The same variables were used for raking in the NHES:95 AE component. Prior to raking, the variables used in the raking procedure were fully imputed. The dimensions and control totals are listed in table 8.

The control totals were obtained from the March 1995 CPS and were allocated according to the October 1994 CPS distributions. In other words, the number in a cell is the proportion in that cell from the October 1994 CPS multiplied by the estimate of the total from the March 1995 CPS. This allocation was necessary because the raking dimensions use items that are only available in the October CPS while the number of adults obtained from the March 1995 CPS is more accurate since it is closer in time to the 1996 survey date. The 1990 Census of Population distribution was used to estimate the distribution of persons across cells defined by urbanicity and Census region.\* The raking iterations were continued until the estimated totals were within 1 of all the control totals.

The final person-level weight for the Adult CI interview for sampled adult  $k$  is:

$$AW_{k(c)} = NAW_k * D_{k(c)},$$

where  $D_{k(c)}$  is the raking adjustment factor for raking cell  $c$ , where adult  $k$  has the attributes corresponding to the levels of the three dimensions of raking cell  $c$ .

---

\* The 1990 Census figures were used to be consistent with the procedures followed for creating the household weight.

## Methods for Computing Sampling Errors

The sampling errors for the NHES:96 can be computed with a jackknife replication method using either WesVarPC or PROC WESVAR. The JK1 method of jackknife replication is appropriate for the NHES:96 because the list-assisted approach used for sampling is a single-stage, unclustered approach. For the JK1 method, the NHES:96 sample of telephone numbers was divided into 19 variance estimation strata corresponding to the 18 states where oversampling occurred and the combination of the 33 states where oversampling did not occur. Eighty replicates were formed based on the stratum, minority status, and sampling order of the telephone numbers. In each replicate, a replicate weight was developed using the same weighting procedures used to develop the full sample weight. Using these replicate weights, estimates can be produced for each replicate and can be compared to the full sample estimate to estimate the sampling error of a statistic of interest.

In NHES:95, fifty replicates were formed. In NHES:96, eighty replicates have been formed. There are three reasons for the increase in the number of replicates from NHES:95 to NHES:96. First, a more precise variance estimate can be obtained with more replicates. Second, the cost of producing variances using more replicates has been reduced due to enhancements to WesVarPC, making the use of more replicates cost-effective. Lastly, since the NHES:96 is designed to produce state-level estimates in addition to national-level estimates, an increased number of replicates was desirable to improve the precision of the variance estimates for these domains.

Replicate weights were created for all four of the final weights: the household-level weights for data from the Screener interview; the person-level weights for data from the Parent PFI/CI interview; the person-level weights for data from the Youth CI interview; and the person-level weights for data from the Adult CI interview. The procedures for forming the replicate weights for each of these four weights are given below.

1. The 161,446 sampled telephone numbers were divided into the 19 strata used for sampling. Each of the first 18 strata is defined by one of the 18 states where oversampling occurred. The 19th stratum is defined by the combination of the 33 states where oversampling did not occur. The telephone numbers in each state or state group (stratum) were first sorted by minority status with the high minority telephone numbers being listed first followed by the low minority telephone numbers. Then, within minority status, the telephone numbers were listed in the same order as that used in the sample selection.
2. Eighty replicates were formed using all 161,446 telephone numbers. This was done by assigning the 1st, 81st, 161st... telephone numbers in the list to replicate 1, the 2nd, 82nd, 162nd... telephone numbers in the list to replicate 2, ... the 80th, 160th, 240th, ... telephone numbers in the list to replicate 80. Thus, there were 2,018 telephone numbers assigned to 74 of the replicates and 2,019 numbers assigned to the remaining 6 replicates. Due to differences in residency and response rates among replicates, however, there is more variation in the number of units per replicate having positive final household weights. This number ranges from 54,954 to 55,061 among the 80 replicates.
3. The telephone numbers for residential households were then assigned 80 weight variables (REPL1 through REPL80) using the following procedures. The replicate base weights were assigned by multiplying the full sample base weight by either zero or 80/79. This procedure is the standard jackknife method of dropping one unit (in this case a group of residential households with the same replicate number) and weighting up the remaining units to account

for the dropped unit. For example, to construct replicate 1 base weights, a replicate base weight of 0 is assigned to residential households from REPL1, and the base weights of all residential households in REPL2 through REPL80 are multiplied by a factor of 80/79.

4. Using the exact same weighting procedures described earlier in this document for each of the four sets of full sample weights, the other adjustments (i.e., sampling adjustments, nonresponse adjustments, and raking adjustments) were applied to every replicate base weight for completed interviews. In other words, the weighting steps described in sections 2 through 5 were applied 80 times, including the raking steps.
5. Two differences in the methods used for the full sample and for the replicate weights were: (a) the raking iterations were stopped when the replicate weights converged to within 10 of the control totals rather than 1, which was used in the full sample weighting; and (b) the trimming of the weights was not applied at the replicate level. Only minor trimming of a small number (183) of Parent PFI/CI interview cases was needed for the full sample weights, indicating that there was not a significant number of cases with very large weights. The trimming of replicate weights involves the review of each replicate as a specific subsample, and is a labor-intensive process. Because the need for trimming at the full sample weight level was very minor (183 cases among the Parent interview weights), the likely benefit of this extensive review process was outweighed by the level of effort involved.

To produce standard errors using a Taylor series program, two variables are required to identify the stratum and the primary sampling unit (PSU). The stratum level variable is the indicator of the variance estimation stratum to which the unit (telephone number of sampled person) is assigned. The PSU is an arbitrary numeric identification number for the unit within the stratum. At the household level, the variance strata are defined by the 30 combinations of state and minority status that were used in sampling.<sup>8</sup> At the person level, minority status alone is used for creating variance strata because there are too few units in the strata as defined at the household level.

On the Household and Library Public File, the stratum and PSU variables are called HSTRATUM and HPSU, respectively. HSTRATUM is defined by the combinations of state and minority status that were used in sampling, which are given in table 1. Within each HSTRATUM, telephone numbers were sorted in the order in which they were selected and were numbered sequentially from 1 through the number of sampled telephone numbers to create HPSU. For example, the stratum defined as "Alaska, high minority" has 15 responding households. Thus, for this stratum, the values of HPSU are 1, 2, ..., 15. For each stratum, the numbering of PSUs begins at 1; thus, HPSU itself is not unique. However, combinations of HSTRATUM and HPSU are unique. The full sample weight for the Household and Library file is FHWT.

The stratum and PSU variables on the Parent PFI/CI File are PSTRATUM and PPSU; the full sample weight is FPWT. On the Youth CI File, the variables are YSTRATUM and YPSU; the full sample weight is FYWT. On the Adult CI File the stratum and PSU variables are ASTRATUM and APSU; the full sample weight is FAWT. The two variance strata for the person-level files are "high minority" and "low minority". On each person-level file, within each minority stratum, the respondents were numbered sequentially from 1 through the number of respondents to create the PSU variable. Thus,

---

<sup>8</sup> Nineteen state categories and two minority status values were used in sampling. However, eight of the states (ME, MT, ND, NH, RI, SD, VT, and WY) have no high minority exchanges. Thus, there are 30 strata.

for example, PPSU itself is not unique. However, combinations of PSTRAUM and PPSU are unique. The stratum and PSU variables can be used in SUDAAN to produce standard errors by specifying that the design is a "with-replacement" sample (DESIGN=WR) and that the sampling levels are given by the appropriate stratum and PSU variables (e.g., for estimates from the Youth CI File, use YSTRAUM YPSU in the NEST statement). Other software packages that use Taylor series methods, such as PCCARP, also use these two variables to define the units needed for computation purposes.

### **Approximate Sampling Errors**

Although the methods of directly calculating the sampling errors using the methods described above are recommended for many applications, simple approximations of the sampling errors may be valuable for some purposes. One such approximation is discussed below.

Most statistical software packages compute standard errors of the estimates based on simple random sampling assumptions. The standard error from this type of statistical software can be adjusted to reflect the complex sample design in order to approximate the standard error of the estimate under the actual sample design used in the survey.

A simple approximation of the impact of the sample design on the estimates of the standard errors that has proved useful in previous NHES surveys and in many other surveys is to adjust the simple random sample standard error estimate by the root design effect (DEFT). The DEFT is the ratio of the standard error of the estimate computed using the replication method discussed above to the standard error computed under the assumption of simple random sampling. A mean DEFT is computed by estimating the DEFT for a relatively large number of estimates and then averaging these DEFT's. Direct computation of the standard errors is recommended when the statistical significance of statements would be affected by small differences in the estimated standard errors.

In complex sample designs, like the NHES:96, the DEFT is typically greater than unity due to the clustering of the sample and the differential weights attached to the observations. The mean DEFT for estimates from the Screener was 1.1, where the average was computed over a range of 54 estimates. The variables used in producing these estimates included household items (XHHACTV, XHHBORN, XHHLANG, HAFDC, HFOODST, HWIC, HHCOMMUN, HINCOME), and public library items (LCOMP, LMATLS, LMOBILE, LPHONE, and LVISIT1). Each estimate was examined for the entire population and by home tenure. The estimated DEFT computed for a particular estimate was typically between 0.9 and 1.2. **A DEFT of 1.1 is recommended for approximating the standard error of estimates from the Screener (the Household and Library data file).**

The design effects for estimates from the Screener by race/ethnicity were slightly higher, with a range of 1.1 to 1.2. To be conservative, a DEFT of 1.2 is recommended for estimates of Screener items by race/ethnicity. For estimates of Screener items for subgroups defined by whether children are present in the household, a DEFT of 1.1 is appropriate. State-level DEFT's ranged from 1.0 to 1.15, with most being approximately 1.0. As a general rule, a DEFT of 1.1 for state-level estimates is recommended.

The mean DEFT for estimates from the Parent PFI/CI interview was 1.2, where the average was computed over a range of 68 estimates. The variables used to estimate the DEFTs included political information, attitude, and participation items (CPAGNST, CPCOMPLI, CPBOYCOT, CPMONEY, CPPUBMTG, CPOTHORG, CPVOTE5, CPTELLIS, CPRDNEWU); knowledge of government items (CPCONST, CPDFENS, CPHOUSE, CPSENATE, CPSPKR, CPVETO, CPVP); home/family activity

items (FOREADTO, FOSTORY, FOAFTHS, FOCHORE, FOCONCRT, FOCRAFTS, FOERAND, FOZOO FOETHNIC, FOLIBRAY, FOMUSEUM); school-related items (SPUBLIC, SRELGON, SCHOICE, SNUMSTUD, SECOLLEG); and parent education (PARGRADE). Each of these measures was examined for subgroups defined by the race/ethnicity of the child and groupings of grade in school. The estimated DEFT computed for a particular estimate was typically between 1.0 and 1.3. To be conservative, **a DEFT of 1.3 is recommended for approximating the standard error of estimates from the Parent PFI/CI interview.** This conservative approach is recommended based on the range of DEFTs and the location of the mean DEFT toward the upper end of the range. The mean DEFT did not vary considerably for estimates from the Parent PFI/CI interview for subgroups defined by race/ethnicity or grade and the same DEFT can be used for all the estimates.

The mean DEFT for estimates from the Youth CI interview was 1.3, where the average was computed over a range of 25 estimates. The variables used to estimate the DEFTs included political information and attitude items (CYANST, CYCOMPLI, CYWATCH, CARDNEWU), knowledge of government items (CYCONST, CYHOUSE, CYJUDGE, CYLAW, CYSENATE, CYSPKR, CYVETO, CYVP), and service activities items (SAARRSER, SACTY, SANEXTYR, SAREQSER, SAREQYOU, SASCHLYR). The estimated DEFT computed for a particular estimate was typically between 1.2 and 1.4. **A DEFT of 1.3 is recommended for approximating the standard error of estimates from the Youth CI interview.** For estimates of characteristics from the Youth CI interview by race/ethnicity, the mean DEFT's were slightly higher, in the range of 1.3 to 1.4. To be conservative, a DEFT of 1.4 is recommended for estimates of Youth CI interview items by race/ethnicity.

The mean DEFT for estimates from the Adult CI interview was 1.2, where the average was computed over a range of 56 estimates. The variables used to estimate the DEFT were political information, attitude, and participation items (CAANST, CACOMPLI, CABOYCOT CAOTHORG, CAMONEY, CAPUBMTG, CARDBOOK, CARDMAGS, CARDNEWU, CAPAP, CATELLIS, CAWATCH); and knowledge of government items (CACONST, CAHOUSE, CAJUDGE, CALAW, CASENATE, CASPKR, CAVP). These estimates were examined by race/ethnicity of the adult. The estimated DEFT computed for a particular estimate was typically between 1.0 and 1.3. **A DEFT of 1.2 is recommended for approximating the standard error of estimates from the Adult CI interview.** The mean DEFT did not vary considerably for estimates from the Adult CI interview for subgroups defined by race/ethnicity, so the DEFT of 1.2 can be used for all estimates.

The average DEFT can be used to approximate the standard error for an estimate. For example, if a weighted estimate of 60 percent is obtained for some characteristic (for example, suppose that 60 percent of children participate in some type of child care arrangement), then an approximate standard error can be developed in a few steps. First, obtain the simple random sampling standard error for the estimate using the weighted estimate in the numerator and the unweighted sample size in the denominator: the simple random sampling standard error for this 60 percent statistic would be the square root of  $((60 \times 40)/20,792 = 0.34$ , where the weighted estimate ( $p$ ) is 60 percent, 40 is 100 minus the estimated percent ( $100-p$ ), and the unweighted sample size ( $n$ ) is 20,792. The approximate standard error of the estimate from the NHES:96 is this quantity (the simple random sample standard error) multiplied by the Parent PFI/CI interview DEFT of 1.3. In this example, the estimated standard error would be 0.44 percent ( $1.3 \times 0.34$  percent). Thus, this calculation is correctly done by hand by using the weighted estimate in the numerator and the unweighted sample size in the denominator to estimate the simple random sampling standard error, and then applying the mean DEFT.

The approximate standard error for a mean can be developed using a related procedure. First, the mean is estimated using the full sample weight in a standard statistical package like SAS or SPSS.

Second, the simple random sample standard error is obtained through a similar, but unweighted, analysis. Third, the standard error from the unweighted analysis is multiplied by the appropriate mean DEFT (1.1 for the Screener, 1.3 for Parent PFI/CI, 1.3 for Youth CI, and 1.2 for Adult CI<sup>9</sup>) to approximate the standard error of the estimate under the NHES:96 design. For example, suppose that the estimated (weighted) mean number of hours the mothers/stepmothers/foster mothers of children work for pay per week was 20 and the simple random sampling standard error (unweighted) was 5 hours. Then, the approximate standard error for the estimate would be 6.5 hours ( $5 \times 1.3$ ). Thus, for means, the unweighted standard error can be obtained from the output of an unweighted analysis, and the mean DEFT is then applied to that unweighted standard error to approximate the standard error of the estimate under the NHES:96 sample design.

Users who wish to adjust the standard errors for parameter estimates of regression models should follow a procedure similar to that discussed for means, above. Specifically, the parameters in the model can be estimated using a weighted analysis in a standard statistical software package such as SAS or SPSS. A similar, but unweighted, analysis will provide the simple random sample standard errors for these parameter estimates. The standard errors can then be multiplied by the appropriate mean DEFT (1.1 for the Screener, 1.3 for Parent PFI/CI, 1.4 for Youth CI, and 1.2 for Adult CI) to arrive at the approximate standard error for the NHES:96 design. For example, if a given parameter in a model involving Parent PFI/CI items has an unweighted standard error of 0.45, then the approximate standard error under the NHES:96 design would be  $1.3 \times 0.45 = 0.59$ . As was the case for means, the unweighted standard error can be obtained from an unweighted analysis using a standard statistical package, and the mean DEFT is then applied to that unweighted standard error to approximate the standard error of the estimate under the NHES:96 sample design.

---

<sup>9</sup> For subgroup analyses by race/ethnicity, the DEFTs may be different, as indicated above.
